13. ABSTRACT (maximum 200 words)

Disc carving is an essential element of computer forensic analysis. However the high cost of commercial solutions coupled with the lack of availability of open source tools to perform disc analysis has become a hindrance to those performing analysis on UNIX computers. In addition even expensive commercial products offer only a fairly limited ability to "carve" for various files.

In this thesis, an open source tool known as Foremost is modified in such a way as to address the need for such a carving tool in a UNIX environment. An implementation of various heuristics for recognizing file formats will be demonstrated as well as the ability to provide some file system specific support.

As a result of these implementations a revision of Foremost will be provided that will be made available as an open source tool to aid analysts in their forensic investigations.

I. INTRODUCTION

As computers become more prevalent in society, their use for criminal and other nefarious purposes also increases. This has lead to a demand for Computer Forensic specialists to analyze digital evidence to help catch these criminals. In response to this demand the FBI and other law enforcement agencies are building Regional Computer Forensic Laboratories across the country. These facilities are equipped with state of the art tools and highly trained examiners to help with an overwhelming case load. In FY 2003, the RCFL Program processed 82.3 terabytes of data; this is the equivalent of roughly 3,427,644 boxes of paper filled with text [Ref. 1]. The San Diego RCFL alone received over 700 requests to review various cases involving the need for computer forensic examinations. This shows the magnitude of the increase in the computer related evidence, and the bad news is, it is only going to get worse for examiners. As hard drives and multimedia storage devices grow exponentially so must the capabilities of the tools which investigators use to analyze these devices. One major area that must be improved is referred to as disc carving.

Disc carving is an essential aspect of Computer Forensics and is an area that has been somewhat neglected in the development of new forensic tools. The term disc carving can be defined as data recovering using "raw" information as opposed to file-system meta-data. Disc carving has a great impact on computer forensic cases because it adds the flexibility of being able to dissect stored information independent of any underlying file system structure. Disk carving has also become synonymous with the term data carving but for the context of this paper the term disc carving will be used. My research in the arena of disc carving will aid investigators in being able to extract useful information from storage devices using an open source product which can automate a large portion of the process. Making this tool and its source code freely available eliminates one of the greatest inhibitors which is the cost of many commercial forensic suites.

New approaches to disc carving must be studied to help develop more efficient and reliable products for investigators to use. These methods can hopefully offset some

of the increasing work load that high volume storage devices pose to limited number of investigators. In addition this research can help in the prosecution of criminals who use computers in some form or another in the conduct of their business.

A. DISC CARVING BACKGROUND

Disc carving refers the ability to recover files from a medium which may or may not be a recognizable file system. It is commonly used in reference to extracting files from unallocated or slack space from a given file system [Ref. 2]. Files are allocated disk space in multiples of the file system block size. Slack space refers to the unused space within the last block allocated to a file. This space lies between the last data byte of the file and the end of its associated block. The amount of slack space a file contains can be computed as (file size) modulo (block size). Thus since all files do not end exactly on block boundaries this "excess" space can be used to hide data from file system view.

Disc carving research has been relegated to the background of forensic tool development. Tools such as ILOOK [Ref. 3], Encase [Ref. 4], and FTK (Forensic Tool Kit) [Ref. 5] focus on recovering files via metadata. It is true that this is a very effective and efficient method of file recovery, however, if the metadata is corrupted or non-existent, then these methods usually fail. Also the data in question could have been "deleted" from the file system view. However, the data could very well be, and often is still intact on the disc, it is just a matter of "carving" it out. In my experimental results data that is years old can often be recovered from unallocated space, depending on the volume size and disc activity.

FTK and Encase address the issues of data carving but these tools are Microsoft Windows based and are very expensive. The cost of these tools and the fact that the extraction methods are closed source is an inhibitor to the forensic community that wishes to use a more robust tool that can perform successful extractions. ILOOK is another Microsoft Windows based tool used in forensic investigations but it is only available to Law Enforcement and government agencies. ILOOK is free to specific government agencies that support a law enforcement directive; however, like FTK and Encase, it is closed source. Thus the ability to learn from and improve extraction

methods is diminished. The fact that the majority of tools currently used by law enforcement are closed source has lead some developers and forensic researches to turn to the open source community.

In the open source world Brian Carrier's Sleuthkit has become a standard tool for doing forensic analysis on UNIX systems. This tool has provided a wealth of resources to examiners that use a UNIX platform and also those faced with fiscal constraints who cannot afford its Windows counterparts. However, one glaring hole in the Sleuthkit is that it provides no carving functionality. Thus investigators looked to a tool named *Foremost* to fill in the gap. Foremost is a very powerful disc carving tool but it is lacking in some respects as chapter II will discuss. The eventual inclusion of disc carving functionality in Sleuthkit will help solidify its place in the forensic community and provide a viable alternative to commercial products.

B. PURPOSE OF STUDY

The purpose of this research is to develop a more intelligent tool to extract files from a medium independent of its file-system structure. Such a tool will greatly reduce the time spent by investigators plowing through binary file representations trying to ascertain what files can and cannot be recovered. Current open source methods of disc carving lack the sophistication needed to provided a robust disc carving program. The general idea to develop such a tool is to mimic the behavior of the *file* command available on UNIX systems but to apply that intelligence to the disc carving tool Foremost. Foremost is a utility that "carves" files out of raw data blocks based on file header and footer data. The file command, which will be covered in depth in chapter II, often looks at more than just the header of the file in order to comprehend the file's internal data structures as well. If the functionality of file and Foremost were combined then a much more powerful tool could be produced. The strategy that emerged as the most fruitful in the development of extraction methods was to perform a more detailed analysis of specific file data structures, allowing for a more in depth recognition as well as increasing the speed of the program. Speed is obviously key when performing analysis of very large disc images, the data structure approach does require the program to become more intelligent but it will save time for the examiner who is currently required to at least have

a working knowledge of file format specifications in order to successfully recover files manually. The automation of this process however challenging, offers great promise in terms of productivity.

My research produced many extraction algorithms which can then be scrutinized and tested via the vast open source forensic community. Creating open source forensic tools is a great way to develop and test tools economically and efficiently. The current implementation of the algorithms described in chapter III can be viewed in the CVS repository of Foremost at http://cvs.sourceforge.net/viewcvs.py/foremost/foremost-1.0/. The availability of the enhancement has lead to increased feedback from the forensic community about features they would like to see as well as problems they encounter.

The outcome of the cycle of publishing and revising the source code will eventually lead to a more robust library of extractions methods that can essentially do the "dirty work" of looking at blocks of data trying to determine if the file is still intact and what type of file is it. Tools like Foremost solve many problems but also introduce new ones. However, these problems may be viewed in a positive light because their solutions lead to more intelligent and efficient products that can aid analysts in data carving.

The debate against open source is usually that the software product may be more prone to exploitation. This is not a major concern with Forensic software as it is not providing a service to multiple clients, just analyzing a local drive. Thus in the case of forensic software, using open source tools just makes more sense.

The goal of a good disc carving tool is to remain file-system independent, which ensures the flexibility of being able to analyze a wider range of storage media. However, options should be added if knowledge of the file-system of a given device is obtained. One example of this is the problem that indirection blocks, used in UNIX file-systems, pose to disc carving. This issue is covered in great detail in chapter three and is another area that commercial forensic products fail to address in the context of disc carving. Thus this paper will describe the implementation of algorithms which will enhance extraction capabilities of an existing Forensic tool, independent of file-system structure, but also, when possible, leveraging certain file-system attributes that can aid the extraction process.

C. THESIS ORGANIZATIONON

This paper will present a working implementation of a disc carving tool that can recover specified files from any block of raw binary data such as, but not restricted to, partial or complete disk images. Chapter II details the operation of Foremost and the file command and explains how a hybrid will benefit the forensic community. Chapter III will provide a description of the important algorithms and the details of their construction. The algorithms include file extraction methods as well as indirection block detection for UNIX file-systems. Full source code examples of each extraction algorithm are provided in Appendix A. Chapter IV will provide a set of experimental results when running the foremost enhancement versus various data carving tools. Different files systems are discussed and tested as well as the details of the indirect block detection capabilities. Chapter V will conclude my research by discussing problems faced as well as describe future work in this are of Computer Forensics.

THIS PAGE INTENTIONALLY LEFT BLANK

II. BACKGROUND

A. FOREMOST

Foremost is an open source forensic tool created for the Linux platform and developed by Special Agents Kris Kendall and Jesse Kornblum of the U.S. Air Force Office of Special Investigations. In accordance with 17 USC 105, this tool is not afforded any copyright protection because it is a work of the U.S. government. The tool was inspired by, and designed to imitate the functionality of, the DOS program CarvThis, written by the Defense Computer Forensics Lab. Foremost enables forensic examiners to automatically recover files or partial files from a bit image (or the media itself) based on file header and footer types specified in a user-defined configuration file.

Foremost works by reading into memory a pre-defined portion of the media or media image under examination. By default this chunk of memory is 10MB, thus images are analyzed 10MB at a time. Each chunk is searched for file headers contained within the Foremost configuration file. If a matching header is found, then Foremost attempts to locate the corresponding end of the file. Foremost will search for the footer (which signifies the end of the file) until a file size limit listed in the configuration file is reached. If the footer is found then the recovered file data is written to a separate disk file, however if it is not then Foremost will dump the maximum file size after the header. If no footer is defined in the configuration file then foremost will extract the maximum number of bytes specified by the configuration file after every header is found. Using a file size limit serves as a means to stop Foremost from adding data to a recovered file if the appropriate file footer is not found. This is a fairly efficient approach if such a header/footer pair is uniquely defined but this is not often the case.

Another limitation of Foremost is the fact that even if a file is successfully extracted, the same data that was just analyzed is checked again. This method is designed to recover embedded files containing the header signature but can be very computationally expensive. This implementation is flawed in the case where Foremost cannot determine the end of the file, thus it merely dumps a predetermined amount of data, this data is then searched for the same header. Files that contain multiple headers

result in fragments of files being written to disk often resulting in the creation of multiple garbage files. This reduces the speed of the program as time is wasted re-analyzing and re-extracting data that has already been extracted as part of a larger file. This added execution time could be better spent ensuring a valid extraction in the first place rather than relying on forensic specialists to wade through redundant fragments of a given file.

Table 1 illustrates some sample Foremost configuration file definitions. The first field denotes the suffix appended to the file if extracted, the second defines whether the search to be performed is case sensitive, followed by the maximum defined file size and lastly the header/footer pair. Notice the definition for *avi* doesn't include a footer; this is a common occurrence in the configuration file. If this is the case then Foremost will just extract the maximum amount following the header, often leading to truncated extractions. Other formats in the configuration file that do not contain an adequate footer include doc, mov, bmp, xls, java.

Suffix	**Case Sensitive**	**Max Size**	**Header**	**Footer**
jpg	Y	20000000	\xff\xd8\xff\xe0\x00\x10	\xff\xd9
htm	N	50000	<html	</html>
avi	Y	4000000	RIFF????AVI	

Table 1. Foremost configuration file

These formats show the flawed method by which these files are extracted. The program then relies on a forensics analyst to extract useful information from the maximum file amount. This amount may not be of sufficient size, thus forcing the analyst to increase the file size and re-run the program iteratively until enough of the file has been extracted. This is an added burden to the time consuming task of performing a detailed analysis of very large storage devices. If this process could be made more intelligent then examiners could spend more time analyzing the evidence rather than extracting it.

B. FILE

File is a program which examines a given file's content in an attempt to classify it based on the actual data in the file rather than merely the suffix (.exe) [Ref. 6]. There are three sets of tests that are performed by *file*: file system tests, magic number tests, and language tests. The first test that succeeds causes the file type to be printed. The idea of the Foremost enhancement is to harness the same type of built-in intelligence provided in the magic number tests.

The determined file type will usually fall into one of the following categories: *text* (the file contains only printable characters and a few common control characters and is probably safe to read on an ASCII terminal), *executable* (the file contains the result of compiling a program into a binary form understandable by some operating system), or *data* meaning anything else (data is usually `binary' or non-printable). Exceptions are well-known file formats (core dump files, tar archives, etc.) that are known to contain binary data. When modifying the /usr/share/magic file or the program itself, it is necessary to preserve these keywords**.** Note that the file /usr/share/magic is built mechanically from a large number of small files in the subdirectory Magdir in the source distribution of this program, these files can be modified by a user knowledgeable about a specific file specification.

The file system tests are based on examining the return from a stat(2) [Ref. 7] system call. The program checks to see if the file is empty, or if it's some sort of special file. Any known file types appropriate to the system you are running on (sockets, symbolic links, or named pipes (FIFOs) on those systems that implement them) are discovered if they are defined in the system header file <*sys/stat.h*>.

The magic number tests are used to check for files with data in particular fixed formats. The canonical example of this is a binary executable (compiled program) *a.out* file, whose format is defined in *a.out.h* and possibly *exec.h* in the standard include directory. These files have a `magic number' stored in a specific, well defined location near the beginning of the file that tells the UNIX operating system that the file is a binary executable, and which of several types thereof. The concept of `magic number' has been adopted by the developers of many other data file formats. Any file with some invariant

identifier at a small fixed offset into the file can usually be described in this way. In the Linux operating system, the information identifying these files is read from the compiled magic file */usr/share/magic.mgc ,* or */usr/share/magic* if the "compiled" file-magic.mgc does not exist. Notice Table 2 which shows how the standard JPEG header is defined in the magic file. More tests are performed to determine more information about the image but the principal of the program is that it looks at the data structures of the file as opposed to just header information.

Offset	**Data Type**	**Data to match**	**Description**
0	Beshort	0xffd8	JPEG image data
>6	String	JFIF	\b, JFIF standard

Table 2. FILE sample magic format

If a file does not match any of the entries in the magic file, it is examined to see if it seems to be a text file. ASCII, ISO-8859-x, non-ISO 8-bit extended-ASCII character sets (such as those used on Macintosh and IBM PC systems), UTF-8-encoded Unicode, UTF-16-encoded Unicode, and EBCDIC character sets can be distinguished by the different ranges and sequences of bytes that constitute printable text in each set. If a file passes any of these tests, its character set is reported. ASCII, ISO-8859-x, UTF-8, and extended-ASCII files are identified as ``text'' because they will be mostly readable on nearly any terminal; UTF-16 and EBCDIC are only ``character data'' because, while they contain text, it is text that will require translation before it can be read. In addition, *file* will attempt to determine other characteristics of text-type files. If the lines of a file are terminated by CR, CRLF, or NUL, instead of the Unix-standard LF, this will be reported. Files that contain embedded escape sequences or overstriking will also be identified.

Once the *file* program has determined the character set used in a text-type file, it will attempt to determine in what language the file is written. The language tests look for particular strings that can appear anywhere in the first few blocks of a file. For example, the keyword "**.**br" indicates that the file is most likely a troff(1) input file, just as the keyword struct indicates a C program. These tests are less reliable than the previous two

groups, so they are performed last. The language test routines also test for some miscellany (such as tar(1) archives). Any file that cannot be identified as having been written in any of the character sets listed above is simply said to be ``data"[Ref 6.].

These tests and the ability to define new tests based on the file offsets prototype for the types of logic that must be incorporated into a program like Foremost to make it more effective. The only thing *file* lacks for our context is a looping structure. In addition it doesn't concern itself with embedded files or where the file data terminates. [1]However applying this functionality is relatively trivial once the data structures of the file are adequately understood. File specifications are the key to utilizing the searching capability that Foremost provides in the most efficient manner.

[1] An embedded file refers to a FILE that is encapsulated within another file.

III. IMPLEMENTATION

A. HEURISTICS

1. OLE Archive

Microsoft's Object Linking and Embedding file format provides for a "structured storage" environment for various types of file formats [Ref. 8]. It is basically an abstraction so that file formats can use the OLE API to read and write data to the disk. This is useful because the formats can then store the data as objects instead of a flat file. It also permits more cross functionality between applications that adhere to this file structure, therefore it is easier to copy objects from a Word document to an Excel file for instance. However this also significantly complicates file extraction because the file structure is much more dynamic.

Previously Foremost only provided the OLE header for Microsoft Word documents and extracted the following the first 50KB relying upon the examiner to determine the end of the file. The algorithms presented here provide a much higher rate of extraction with increased accuracy of the data recovered. These algorithms make use of an API developed by the Chicago Project (http://chicago.sourceforge.net/) whose goal is to develop a C library to read and write Microsoft Excel documents [Ref. 9]. This API was modified to add error detection and the ability to analyze an array of bytes as opposed to a stand alone file. This enables Foremost to use this API to extract file dependent information and determine what type of file was stored in an OLE structure.

Parsing the OLE data structures proved complicated but extremely rewarding because the extraction of any interesting Microsoft File Format adhering o the OLE format became trivial. The algorithm works by first reading the header block which is always 512 bytes. The block size of the remaining document is defined in the header but it is usually 512 bytes as well. This value is specified by the uSectorShift field located in the header block which is outlined in Table 3 below. This table also provides information about what data values are located within the OLE header and Table 4 provides a hexadecimal display of an OLE header taken from a Word Document. Table 4 also shows the magic number, uByteOrder, num_FAT_blocks, and the root_start_block in

bold as these fields are crucial to begin parsing the OLE data structures as they provide where to begin reading information and how to interpret it. Using the information in the header we can then build the FAT (File Allocation Table) of the OLE document.

Offset	Data Type	Name	Comments
0	Char	magic[8]	Must equal 0x **d0 cf 11 e0 a1 b1 1a e1**
8	Char	clsid[16]	class id field is generally not used
24	Ushort	uMinorVersion	Minor version of the format: 33 is written by reference implementation. Used mainly for error checking purposes in a disc carving context.
26	Ushort	uDllVersion	major version of the dll format: 3 is written by reference implementation
28	Ushort	uByteOrder	indicates Intel byte-ordering
30	Ushort	uSectorShift	size of sectors in power-of-two (typically 9, indicating 512-byte sectors)
32	Ushort	uMiniSectorShift	size of mini-sectors in power-of-two (typically 6, indicating 64-byte mini-sectors)
34	Ushort	Reserved	reserved, must be zero
36	Ulong	reserved1	reserved, must be zero
40	Ulong	reserved2	reserved, must be zero
44	Ulong	num_FAT_blocks	number of SECTs in the FAT chain
48	Ulong	root_start_block	first SECT in the FAT Directory chain
52	Ulong	dfsignature	signature used for transactioning must be zero. The reference implementation does not support transactioning
56	Ulong	miniSectorCutoff	Maximum size for mini-streams: typically 4096 bytes.
60	Ulong	dir_flag	first SECT in the mini-FAT chain
64	Ulong	csectMiniFat	number of SECTs in the mini-FAT chain
68	Ulong	FAT_next_block	first SECT in the DIF chain
72	Ulong	num_extra_FAT_blocks	number of SECTs in the DIF chain
76	Ulong	sectFat[109]	FAT block list starts here. first 109 entries

Table 3. OLE Header Structure (After: Ref. [8])

Offset	Hexadecimal
0	**d0 cf 11 e0 a1 b1 1a e1** 00 00 00 00 00 00 00 00
16	00 00 00 00 00 00 00 00 3e 00 03 00 fe ff **09 00**
32	06 00 00 00 00 00 00 00 00 00 00 00 **01 00 00 00**
48	**5a 00 00 00** 00 00 00 00 00 10 00 00 5c 00 00 00
64	01 00 00 00 fe ff ff ff 00 00 00 00 59 00 00 00

Table 4. OLE Header Hexdump

The FAT contains the allocation information within a compound file. Every sector in the file is represented within the FAT in some fashion, including those sectors that are unallocated (free). The Fat is a virtual stream made up of one or more FAT Sectors [Ref. 8]. FAT sectors are arrays of SECT's that represent the allocation of space within the file. Each stream is represented in the FAT by a chain, in much the same fashion as a DOS file allocation table (FAT). To elaborate, the set of FAT sectors can be considered together to be a linked list—where each node in the list contains the SECT of the next sector in the chain, and this SECT can be used as an index into the Fat array to continue along the chain [Ref. 5].

Once the File Allocation Table is parsed, it is used to extract objects embedded within the file. This is done by examining the directory lists and then reading each entry within them. The entries themselves hold the application specific information we are looking for to determine what type of file it is (doc, ppt, xls…). The FAT is essentially an array of pointers to the directory listings which in turn are arrays of pointers to the entries themselves. The complexity of this hierarchy of pointers is the reason the Chicago Project developed the OLE API. Programmers need not learn the OLE file structure in order to achieve simple tasks of reading and writing to objects within the document. The entries can then be parsed and their name, size, and offset are stored to help determine the type of the file and size. Notice the listing in Figure 1 below which shows the output of a program called ole-dump which was written for the Chicago Project. It basically reads each entry of each directory structure and dumps the

information to the screen. The OLE extraction algorithm uses the basic functions of this program to help discern the size and type of the file. Notice that DIRENT_2 has the title "WordDocument", all word documents contain some variation of this name as an object in one of their entries. Therefore it can be used as an identifier for Microsoft Word Documents.

Figure 3. ole-dump output of an Power Point Document

Each of these documents has a very similar structure. They usually contain summary information which includes information about the author, the file name, when the file was last modified. Other methods to try to use the document summary information as a type of makeshift footer are not reliable as this information can appear at any location in the file.

The flexibility of the OLE file-structure also introduces the need for added error detection. OLE files are complex in nature and must be verified to ensure proper parsing and extraction. The consistency of various fields such fields as the block size of the

document, the number of FAT blocks, and the mini-FAT cutoff can be used to perform error checking. This provides added assurance that the algorithm is not wasting its time parsing corrupted data.

The extraction of OLE files offers great promise. Because the Microsoft Office suite is so popular, documentation used by criminals can often be found in this format. This also enhances the forensic capabilities of the UNIX/LINUX platform as reliable OLE detection/extraction is only currently available on the Windows platform. In addition, with the advent of OpenOffice [Ref. 10] which provides support for the Microsoft Office suite these documents are often authored on UNIX systems as well. Thus this detection capability provides an invaluable resource to those performing forensic analysis.

2. PDF (Adobe Portable Document Format)

PDF is a file format used to represent a document in a manner independent of the application software, hardware, and operating system used to create it [Ref. 11]. A PDF file contains a PDF document and other supporting data. It is basically a binary file which also uses ASCII tags as delimiters to describe the header and trailer data structures in an SGML inspired fashion.

One of the main issues that earlier versions of Foremost had was that some formats (including PDF) often have multiple footers. This creates an obvious problem: how to determine which footer actually represents the end of the file. As a result Kornblum and Kendall developed a REVERSE search mechanism [Ref. 12] to allow them to find the last footer found in a given buffer. The REVERSE method essentially looked for the last footer in the buffer and associated it with the given header. This proved to be successful some of the time, but severely degraded its usefulness as the buffer size grew. Often multiple PDF files would be extracted as one file. In other cases, the footer appended was that of a corrupted PDF, causing the extracted file to be un-readable.

Further research of the PDF file specification revealed that a PDF contains multiple footers only if it has been “linearized”. [Ref. 11] A linearized PDF file is one

that has been organized in a special way to enable efficient incremental access in a network environment. Thus linearized PDF files are very common.

The PDF extraction function searches for the keyword "Linearized" in the header. If it is found, then the length of the file is stored in the header preceded by a "\L " character sequence. This approach obviously increases the speed of Foremost as the program no longer needs to crunch through the entire PDF attempting to guess where it terminates. In this case, the function simply performs a search for the "\L" sequence and parses the number that follows, which is the file size in bytes. See Figure 4 for a structural description of a Linearized PDF.

.

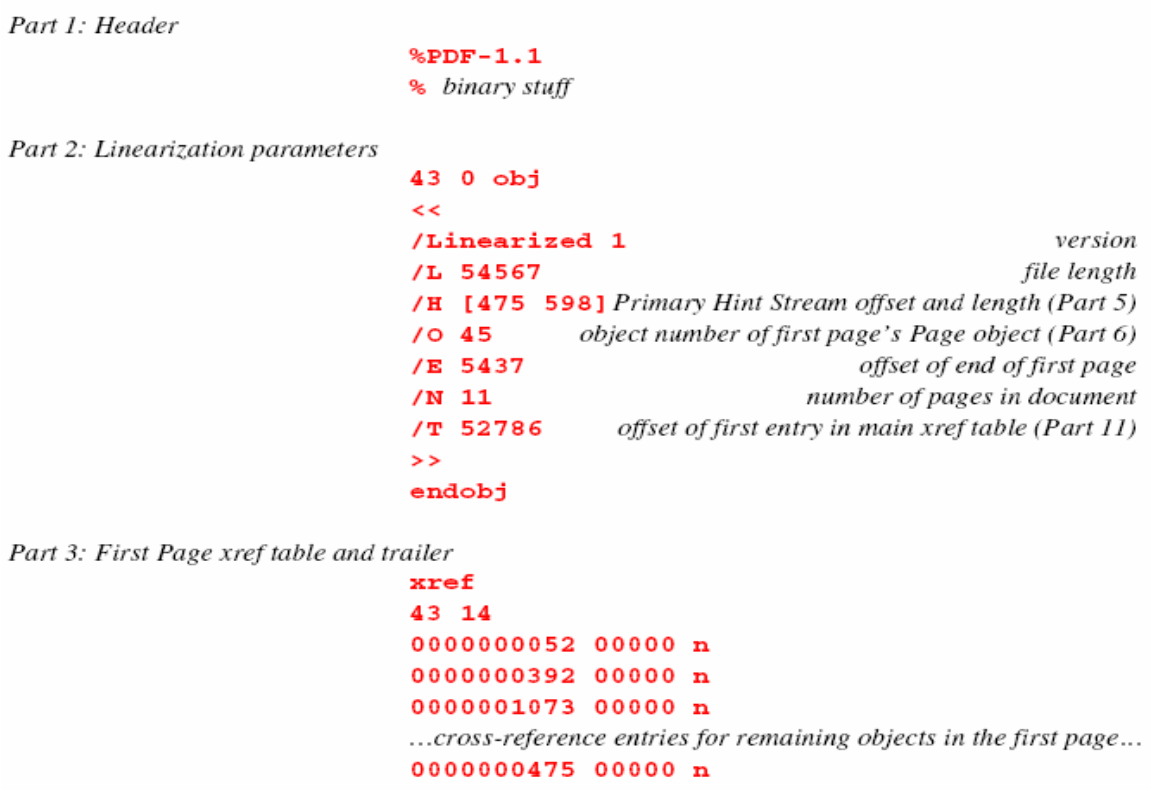

Figure 4. Linearized PDF (From Ref. [11])

The PDF file format is more reminiscent of an XML document than a traditional binary document. This is why the common approach of being able to jump among data structures does not apply to this format. However, since linearized PDF files are

becoming more prevalent, this algorithm will perform very quickly since the file size for this kind of file is often found within the first 100 bytes and no more file processing is necessary to extract these files which are often on the order of several megabytes in size.

Even when a file is not linearized the heuristic performs well in terms of successful extraction because of the unique trailer defined by the PDF specification (%%EOF). Hence a straight forward Boyer Moore search (described further in Chapter III) for the end of the file can be performed. This approach was successfully used to extract PDF's prior to PDF version 1.2 because the Linearized capability was not implemented.

Some minor error checking is also implemented. The first 100 bytes must include an "obj" tag, the fundamental storage tag for all PDF elements. An example of a non-linearized header is given below in Figure 5. Notice that the obj reference is still intact in this case making it a valuable marker to determine whether or not the file has been corrupted.

Offset	**Hexadecimal**	**ASCII**
00	25 50 44 46 2D 31 2E 33 0A 25 C7 EC 8F A2 0A 36	%PDF-1.3.%Çì□¢.6

Figure 5. Non Linearized Header

3. JPEG

JPEG stands for Joint Photographic Experts Group, which is a standardization committee. It also stands for the compression algorithm that was invented by this committee. To complicate things a bit more, JPEG compressed images are often stored in a file format called JFIF (JPEG File Interchange Format). JPEG data structures are composed of segments that are marked by identifiers [Ref. 13]. A listing of these markers is provided in Table 5. Each of these markers is preceded by a byte which

equals “0xff”. For example a common JPEG header may look like “0xff d8 ff e0 00 10 4a 46 49 46” (Hexadecimal), this is the simple case. The old method, implemented in earlier versions of Foremost, of grabbing a file based on header and footer information works well.

Marker Name	Marker Identifier	Description
SOI	0xd8	Start of Image
APP0	0xe0	JFIF application segment
APPn	0xe1 – 0xef	Other APP segments
DQT	0xdb	Quantization Table
SOF0	0xc0	Start of Frame
DHT	0xc4	Huffman Table
SOS	0xda	Start of Scan
EOI	0xd9	End of Image

Table 5. JPEG Marker Information (After: Ref.[13])

However, with the advent of digital cameras and the introduction of changes to the JPEG [Ref. 14] specifications, this method is no longer satisfactory. The new formats now allow for multiple headers, footers and even nested images, to support thumbnails for example. Digital cameras often utilize the APP segment marker “0xe1” to signify that they include more meta-data than the standard JFIF. Table 6 shows the hexadecimal representation of a JPEG taken from a Cannon digital camera; notice that the JPEG header repeats itself in the first block. The footers are also repeated for a total of 3 header/footer pairs in this specific file. Most tools that use the header/footer method of extraction, will extract three files out of this one image, one of those being a valid thumbnail while the others will appear as corrupt. For these reasons a more intelligent algorithm must be provided.

However, these compound formats still adhere to the common JFIF header structure. Thus even multiple headers and footers pose no problems to the implementation described below. Complex files can even increase the speed of the algorithm because, as more of the data can be skipped, less to be processed via the Boyer-Moore algorithm.

Offset	Hexadecimal View of JPEG Data
0	**ff d8 ff e0 00 10 4a 46 49 46** 00 01 02 01 00 48
10	00 48 00 00 **ff e1** 0b d5 45 78 69 66 00 00 4d 4d
20	00 2a 00 00 00 08 00 0a 01 0f 00 02 00 00 00 06
180	00 00 00 01 00 00 00 48 00 00 00 01 **ff d8 ff e0**
190	**00 10 4a 46 49 46** 00 01 02 01 00 48 00 48 00 00
be0	49 15 32 49 45 24 94 ff 00 **ff d9** ff ed 10 4c 50
1160	5f 00 18 00 01 **ff d8 ff e0 00 10 4a 46 49 46** 00
1bc0	ff 00 **ff d9** 00 38 42 49 4d 04 21 00 00 00 00 00

Table 6. Canon Digital Camera JPEG representation

The JPEG extraction algorithm exploits the fact that each JPEG marker contains the size of the header that the marker identifies. This allows the algorithm to jump from header to header until an invalid header is reached. If the file is a valid JPEG then the last marker parsed will be the SOS (Start of Scan) marker which signifies the beginning of the actual image data. Once this marker is reached then a Boyer Moore search for the "0xff d9" marker (which signifies the EOF) ensues.

With this ability to parse the JPEG data structures, our enhanced version of Foremost can now perform some error checking to ensure the file being extracting has not been corrupted. For instance each JPEG image must contain a Huffman Table marker as well as a Quantization Table, these checks are simple, efficient, and reduce the amount of information that the forensic examiner must process manually.

This method of extraction increases the accuracy of extraction as well as the speed as entire headers are skipped instead of being processed by the searching algorithm. Headers are kilobytes in size, so the fact that they are parsed rather than searched and interpreted byte by byte offers significant computational savings.

4. GIF

The Graphics Interchange Format (GIF) defines a protocol intended for the on-line transmission and interchange of raster graphic data in a way that is independent of the hardware used in their creation or display. There are two common versions of this format the 87a and 89a revision [Ref. 15]. This format has remained unchanged for the last decade and thus has proven to be a rather easy file to extract. It is one of the few which has a defined header and footer. Both of which occur only once in the file. Thus header and footer information is sufficient to successfully extract these files.

Table 7 illustrates header and footer information from a common GIF image. The GIF extraction algorithm searches for the unique string "\x47 \x49 \x46 \x38" (GIF8), once this is reached further tests are performed to determine if it is in fact a valid GIF file and whether it is revision 87a or 89a. Once this validation is performed a Boyer Moore search is ensues to find the unique "\x00 \x3b" identifier to determine the end of the GIF stream.

Offset	**Hexadecimal**
0	**47 49 46 38** 39 61 6c 02 22 03 a2 00 00 ff ff ff
	…
48e0	60 05 5c 02 00 **00 3b** 00

Table 7. GIF File Format

The only improvement we made to this extraction method is the fact that each version is analyzed in one pass through the data. Previous versions of Foremost would have to do independent searches for each header (87a and 89a). These are combined in the enhancement so search time is reduced by not analyzing the same information multiple times.

5. BMP (Windows Bitmap Files)

A BMP (Windows Bitmap File) [Ref. 16] is comparatively one of the more trivial files to successfully extract. Table 8 shown below illustrates the information provided in a BMP header. Notice the bfSize field in bold print, as this is the size of entire file in bytes. This is located at the offset 2 in the file! It may seem that extraction can be performed once this information is determined but additional checks must be provided to help ensure that the file being extracted is indeed valid BMP. The fact that header is only marked by two bytes "\x42 \x4d" (BM) means that a lot of false positives will be handed to the extraction function so a lot of "sanity" checking must be performed. Thus the horizontal and vertical sizes of the BMP are checked to see if they are reasonable values. If they are, then we have an added level of assurance that the file is indeed a Bitmap. More error checking could be added to take advantage of the data in the rather large header BMP files provide.

Offset	Field	Size	Contents
0000h	Identifier	2 bytes	'BM' - Windows 3.1x, 95, NT, …
0002h	File Size	1 dword	Complete file size in bytes.
0006h	Reserved	1 dword	Reserved for later use.
000Ah	BitmapData Offset	1 dword	Offset from beginning of file to the beginning of the bitmap data.
000Eh	Bitmap Header Size	1 dword	Length of the Bitmap Info Header used to describe the bitmap colors, compression, … The following sizes are possible: 28h - Windows 3.1x, 95, NT, … 0Ch - OS/2 1.x F0h – OS/2 2.x
0012h	Width	1 dword	Horizontal width of bitmap in pixels.
0016h	Height	1 dword	Vertical height of bitmap in pixels.
001Ah	Planes	1 word	Number of planes in this bitmap.
001Ch	Bits Per Pixel	1 word	Bits per pixel used to store palette entry information. This also identifies in an indirect way the number of possible colors. Possible values are:
001Eh	Compression	1 dword	Compression specifications. The following values are possible: 0 - none (Also identified by BI_RGB) 1 - RLE 8-bit / pixel (Also identified by BI_RLE4) 2 - RLE 4-bit / pixel (Also identified by BI_RLE8) 3 - Bitfields (Also identified by BI_BITFIELDS)
0022h	Bitmap Data Size	1 dword	Size of the bitmap data in bytes. This number must be rounded to the next 4 byte boundary.
0026h	HResolution	1 dword	Horizontal resolution expressed in pixel per meter.
002Ah	VResolution	1 dword	Vertical resolution expressed in pixels per meter.
002Eh	Colors	1 dword	Number of colors used by this bitmap. For a 8-bit / pixel bitmap this will be 100h or 256.
0032h	Important Colors	1 dword	Number of important colors. This number will be equal to the number of colors when every color is important.
0036h	Palette	N * 4 byte	The palette specification. For every entry in the palette four bytes are used to describe the RGB values of the color in the following way:
0436h	Bitmap Data	x bytes	Depending on the compression specifications, this field contains all the bitmap data bytes which represent indices in the color palette.

Table 8. BMP Header Information(After: Ref. [16])

An example of a bitmap header is given in Table 9 showing that the file size according the bytes 2-6 is 163,878 which has the hexadecimal representation "0x26 0x80 0x02 0x00" in little endian format. Also highlighted are the horizontal and vertical sizes of the BMP located at offsets 18 and 22 in the file. With this information we can deduce that the Bitmap is 400x407 pixels which is a reasonable value for a bitmap image. As noted previously these are invaluable for error detection.

Offset	Hexadecimal
0	**42 4d** ***26 80 02 00*** 00 00 00 00 36 04 00 00 28 00
16	00 00 **90 01 00 00 97 01 00 00** 01 00 08 00 00 00
32	00 00 f0 7b 02 00 20 2e 00 00 20 2e 00 00 00 01
48	00 00 80 00 00 00 00 00 00 00 73 73 73 00 29 23
64	28 00 ce be bf 00 b5 a2 a5 00 0f 09 0e 00 52 4c
80	51 00 9d 8a 8d 00 49 39 3a 00 d7 d4 d0 00 62 5c

Table 9. BMP Header in hexadecimal

The previous version of Foremost would merely check for the BM header and then dump the next 50KB into a file and make the examiner determine the EOF. The current implementation is an obvious improvement as the examiner can simply look at the files content in an image viewing application as opposed to trying to interpret hexadecimal values and deduce file specific information from them. This drastically reduces the examiners workload because the majority of data they are looking for may be graphical in nature, especially in cases where pornography is involved.

6. MOV (QuickTime Movie files)

A QuickTime file [Ref. 17] is simply a collection of atoms, the basic data structures of the file. QuickTime does not impose any rules about the order of these atoms. This allows for ease of concatenation when editing movie files. See Figure 6 for a typical structure of a QuickTime movie file.

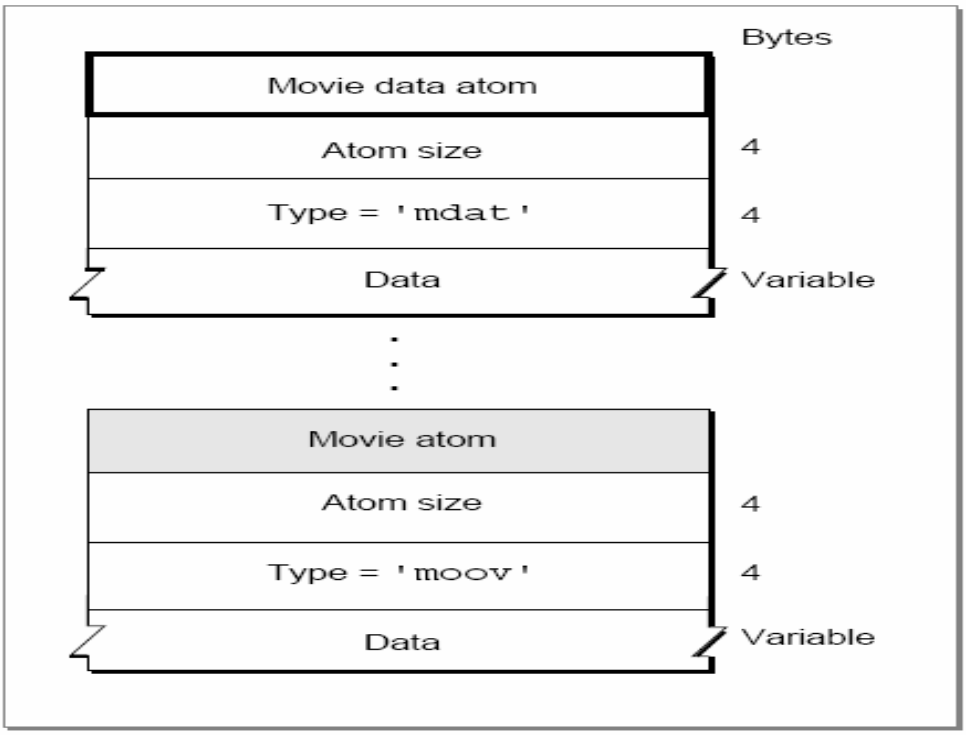

Figure 6. QuickTime Movie Structure (From: Ref. [17])

This modular file format provides flexibility to the application but is difficult to parse using traditional methods, as no unique marker is used to signify where the file terminates. However, if the atoms are parsed, the size of each atom is included in the atom header. This provides the ability to jump from atom header to atom header until an invalid header is reached. Once this occurs, the EOF has been determined. This method also is highly optimized as MOV files are often large.

Another problem, the flexibility QuickTime files creates, is the fact that the structure of the headers can vary somewhat. The standard atom header is of type 'moov' but modern digital cameras implement what is called VJPEG (Video JPEG) format which uses the atom type 'pnot' as the first atom in the file. For this reason these two extraction methods are performed separately but will both be invoked when searches for "multimedia" files are performed.

Notice from Figure 6 that the same format of length, then type, and then data (value) is used as the basic structure of an atom. Table 10 provides a step by step walk through of how a MOV file is parsed through iteration of the extraction function. The

test case was a VJPEG file that was 9,275,716 bytes in size. Each iteration shows that the first four bytes of the header contains the header size in big endian format while the remaining four bytes contain the type of the atom in ASCII text.

The first iteration determines main header information located at offset 0. The size of the header is extracted (in this case 20) and then the file pointer is moved accordingly to offset 20. At offset 20 a PICT atom is located and is 6196 bytes in size. Jumping again to offset 6216 is the main data portion of the MOV file which is of type "mdat". All valid MOV files must contain this atom; therefore, it is used as an error checking mechanism to determine if the file to be extracted is intact. The last atom is of type "moov" which is the standard header for most MOV files, but as shown here can be included anywhere in the file. Jumping the size of the "moov" atom puts the file pointer at the end of the file. Summing the size of each atom yields an original file size of 9,275,716 bytes.

Header#	Size	Type	Header in Hexadecimal
0	20	pnot	0 0 0 14 70 6e 6f 74
1	6196	PICT	0 0 18 34 50 49 43 54
2	9266184	mdat	0 8d 64 8 6d 64 61 74
3	3316	moov	0 0 c f4 6d 6f 6f 76
Total	9275716		

Table 10. MOV Extraction Algorithm Step-through

7. WMV (Windows Media Video)

Windows Media Video/Windows Media Audio files use the ASF file format[Ref. 18]. The Advanced Streaming Format (ASF) is an extensible file format designed to store synchronized multimedia data. It supports data delivery over a wide variety of networks and protocols while still proving suitable for local playback. ASF supports advanced multimedia capabilities including extensible media types, component download, scaleable media types, author-specified stream prioritization, multiple language support, and extensive bibliographic capabilities, including document and content management.

The invaluable (for us) data structure in the ASF format contains the header "0xA1 DC AB 8C 47 A9". The structure beginning with this header contains the file properties object header and the file size (in bytes). Thus it can be used to determine the EOF. This header is often found within the first 512 bytes of the file and thus processing often extremely large WMV/WMA files is avoided. See the Figure 7 below for a description of the ASF format.

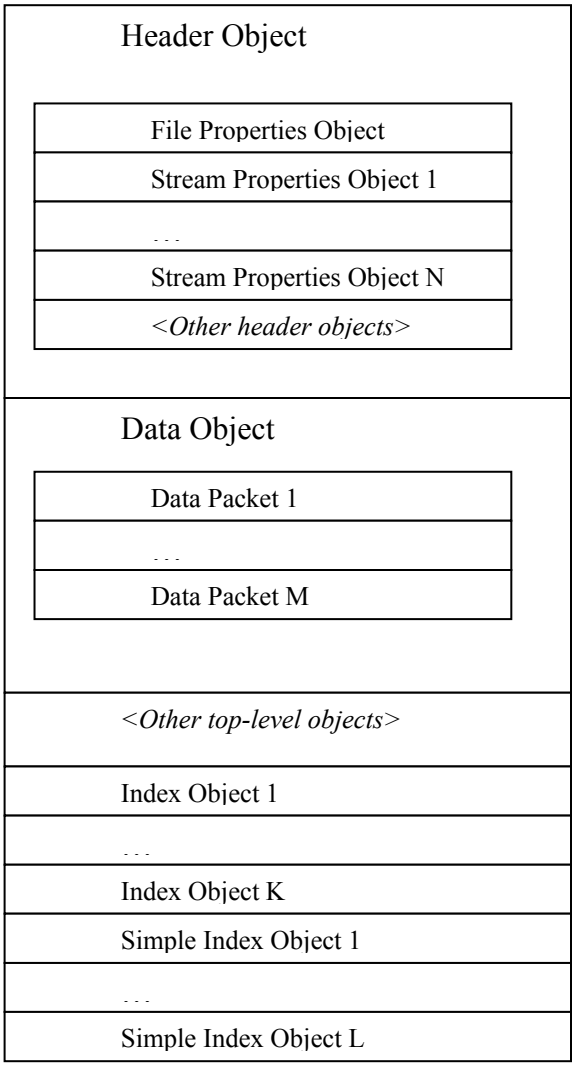

Figure 7. ASF File Structure (From: Ref. [18])

The basic idea behind the algorithm we use to parse these files is that once the file header is found ("\x30\x26\xB2\x75\x8E\x66\xCF\x11"), a search for the file properties header which contains the file size information is executed. This is shown in Table 11 below. Once the file properties object has been located, the file size is located at offset 40 within the object. This information helps determine the end of the file. The trick is that the file properties object can be located at various offsets throughout the beginning of the file, which is why a search for the header ID must be used to determine its location.

Name	Size (bytes)
Object ID	16
Object Size	8
File ID	16
File Size	**8**
Creation Date	8
Data Packets Count	8
Play Duration	8
Send Duration	8
Preroll	8
Flags	4
Minimum Data Packet Size	4
Maximum Data Packet Size	4
Maximum Bitrate	4

Table 11. ASF File Properties Object Structure (After: Ref. [18])

See Table 12 below for a sample header of a WMV file and the import values in bold. Once the file properties object is found at offset 69, we know from the structure of the file properties object that the file size is stored at offset 109 in an eight byte value in little endian format. Thus a simple pointer addition can be used to arrive at the file size of the WMV.

Offset	Hexadecimal

Table 12. ASF Header in Hexadecimal

This added knowledge of the internal data structures has provided us the means to enhance Foremost so that it can avoid searching through, in many cases, megabytes of information to determine a files endpoint. Previous versions of Foremost provide no support for WMV/WMA files. This new ASF capability opens the door to the multimedia files. This will aide in the prosecution of pornography cases. In addition, with the increasing popularity of WMA files for pirating music Foremost 1.0 can be a useful tool in the prosecution of copyright violations.

8. ZIP

Zip files often contain multiple embedded files of varying formats; these are structured in an incremental fashion, followed by a "central directory structure". ZIP archives are a standard format for compressing and storing multiple files. Each file contained within the zip has its own valid ZIP header with its compressed and uncompressed data sizes stored within it. This information can be exploited to increase the speed of the extraction of ZIP files.

```
[local file header 1]
[file data 1]
[data descriptor 1]
.
.
.
[local file header n]
[file data n]
[data descriptor n]
[central directory]
[zip64 end of central directory record]
[zip64 end of central directory locator]
[end of central directory record]
```

Figure 8. Basic Zip File Structure (From Ref. [19])

The algorithm works incrementally by parsing each local file header, using the compressed size field located at offset 20. This value is then used to jump to the next local file header. Once all the files headers have been analyzed then a Boyer Moore search for the identifier of the end of the central directory record is conducted. Once this object is located (the structure is given in Table 13) the algorithm then reads the length of the comment field and jumps to that value plus the size of the object (20 bytes). The result is the end of the zip file.

Field Description	**Size**
central file header signature	4 bytes (**0x02014b50**)
version made by	2 bytes
version needed to extract	2 bytes
general purpose bit flag	2 bytes
compression method	2 bytes
last mod file time	2 bytes
last mod file date	2 bytes
crc-32	4 bytes
compressed size	**4 bytes**
uncompressed size	4 bytes
filename length	2 bytes
extra field length	2 bytes
file comment length	2 bytes
disk number start	2 bytes
internal file attributes	2 bytes
external file attributes	4 bytes
relative offset of local header	4 bytes

Table 13. ZIP local file header structure (From Ref.[19])

The structure an outline of the central directory structure, is given below in Table 14. The header value "0x50 4b 05 06" is used to flag the beginning of the structure at which point the comment field is extracted to determine the exact EOF.

Field Description	**Size**
end of central dir signature	4 bytes (**0x06054b50**)
number of this disk	2 bytes
number of the disk with the start of the central directory	2 bytes
total number of entries in the central directory on this disk	2 bytes
total number of entries in the central directory	2 bytes
size of the central directory	4 bytes
offset of start of central directory with respect to the starting disk number	4 bytes
.ZIP file comment length	**2 bytes**
.ZIP file comment	(variable size)

Table 14. End of Central Directory Object Structure (From Ref.[19])

A sample run through of the algorithm is provided below with a zip archive containing 9 files with a total size 679168 bytes. As show in the Table 15 each iteration jumps to the next file in the archive. A total of 10 iterations are required because of the initial zip file header. Each file size is the summation of the compressed file size (located at offset 20 within the local file header as show in Table 13), the file name length, the extra length, and the size of the data structure itself (30 bytes). These ten jumps amount to a total file size of 678439 bytes, there are some peripheral data structures at the end of the file so a Boyer Moore search is done to find the end of the central directory structure. This proves trivial as 729 bytes remain after the jump loop takes place, thus the vast majority of the search overhead is avoided.

Header#	Size	Header in Hexadecimal
0	65002	**50 4b 3 4 14** 0 0 0 8 0 34 87 30 32 12 16
1	27041	**50 4b 3 4 14** 0 0 0 8 0 34 87 30 32 49 e2
2	20516	**50 4b 3 4 14** 0 0 0 8 0 34 87 30 32 ed 65
3	186436	**50 4b 3 4 14** 0 0 0 8 0 34 87 30 32 c5 15
4	17202	**50 4b 3 4 14** 0 0 0 8 0 34 87 30 32 2d 72

7	55707	**50 4b 3 4 14** 0 0 0 8 0 35 87 30 32 25 6f
8	7143	**50 4b 3 4 14** 0 0 0 8 0 35 87 30 32 47 77
9	416	**50 4b 3 4 14** 0 0 0 8 0 35 87 30 32 21 8b
Total	678439	

Table 15. ZIP extraction algorithm step-through

Obvious improvement can be seen implementing this extraction method as opposed to traditional methods. Much of the searching burden is relieved by the ability to merely jump to each file objects until only a few small data structures remain to parse. Comparing this to the previous method which Foremost used is not even worthy of comparison as the speed of extraction is increased exponentially. Since zip files have no well defined footer, the examiner was previously forced to attempt to determine where the file ended by incrementally extracting more of the file and running zip decompression algorithms against it. This is time consuming and should be avoided if possible.

9. GZIP

The GZIP file format is recursive in nature as it is merely processed until the decompression algorithm completes. No notion of the original data size is given to the algorithm, therefore in order to fully support the extraction of GZIP files a decompression algorithm must be incorporated into Foremost. Currently this introduces system dependent issues and is left as future work. However, a simplified extraction method is possible with marginally good results.

The GZIP header value is equal to “0x1f 8B” which is used to identify the file as a gzip file. This identifier is followed by a one byte value which identifies the compression method used in the file. CM = 0-7 are reserved. CM = 8 denotes the "deflate" compression method, which is the one customarily used by gzip. If this

information is parsed and verified to be a gzip header with some degree of assurance we can then jump to the end of the header and search for the string "\x00 \x00 \x00 \x00". This works reasonably well as files in the GZIP format do not write blocks of zero's in the data portion of the file, however empty sectors on the disc usually contain all zeros. The fact that this often overshoots the end of the file in most cases is irrelevant since the decompression algorithm ignores extraneous information, the file will inflate without a problem.

Offset	Hexadecimal
0	**1F 8B** 08 08 E6 38 BA 3B 00 03 69 74 73 34 2D 31

Table 16. GZIP Header in Hexadecimal

The GZIP file format is most common on a UNIX platform and is therefore a valuable commodity to open source tools that analyze such environments. This algorithm while still a "best effort" provides support for a format that was not supported in older versions of Foremost. The method is still the same in terms of using basic header and footer information to deduce the file size. However, the error checking capabilities in terms of checking to see if the header contains reasonable values significantly reduces the number of false positives generated by the program.

10. RIFF

The RIFF file structure is used by various file formats, most notably AVI (Audio/Video Interleaved) and WAV. The WAV File Format is a file format for storing digital audio (waveform) data. This format is very popular as it is most commonly used in commercial music cd's. It is also widely used in professional programs that process digital audio waveforms. WAVE files are often just RIFF files with a single "WAVE" chunk which consists of two sub-chunks -- a "fmt" chunk specifying the data format and a "data" chunk containing the actual sample data [Ref. 20]. Table 17 below shows a sample WAV header stored in the RIFF file structure. The first four bytes indicate the RIFF file structure, followed by the file size stored in little endian, and finally the WAV signature indicating that this is indeed a WAV file within the RIFF structure.

Offset	Hexadecimal	Ascii
00	**52 49 46 46 B0 A3 01 00 57 41 56 45** 66 6D 74 20	**RIFF**°£..**WAVE**fmt
16	10 00 00 00 01 00 02 00 44 AC 00 00 10 B1 02 00	.....D¬...±..
32	04 00 10 00	....

Table 17. Wave File Header

The Audio/Video Interleaved (AVI) file format is a RIFF file specification used with applications that capture, edit, and playback audio/video sequences. In general, AVI files contain multiple streams of different types of data. Most AVI sequences will use both audio and video streams[Ref. 21]. The AVI RIFF form is identified by the four-character code "AVI " as noted below in Table 18. All AVI files include two mandatory LIST chunks. These chunks define the format of the streams and stream data and are also used to provide an error checking mechanism to the extraction function.

Offset	Hexadecimal	Ascii
00	**52 49 46 46** 8A E7 86 09 **41 56 49** 20 4C 49 53 54	RIFFŠç†.**AVI** LIST
16	26 01 00 00 68 64 72 6C 61 76 69 68 38 00 00 00	&...hdrlavih8...
32	6B 04 01 00 C3 DA 34 00 00 00 00 00 10 08 00 00	k...ÃÚ4.....

Table 18. AVI File Header

Extracting an AVI/WAV file is trivial because the file size is stored in the RIFF file format at offset 4. Thus minimal error checking is required to ensure that the file is indeed an AVI or a WAV before it is extracted. This type of error checking includes, in the case of an AVI, the verification that the header contains the LIST chunk a mandatory portion the file specification.

This algorithm is an obvious improvement over the previous version of Foremost as WAV files were not supported and AVI files do not contain valid footers, therefore as we have seen previously the burden is then needlessly placed upon the examiner. Also the speed of the extraction function is a major enhancement as only the first block of data needs to be analyzed to determine the actual file size.

11. HTML

Extracting HTML (Hyper Text Markup Language) files requires the challenging tasks of building heuristics to look at file content as opposed to its data structures. HTML files are fairly intuitive to extract as they have a defined footer. This is not the case with most other ASCII files. The main problem in dealing with HTML is the generation of false positives. To deal with this the new extraction algorithm checks the first block of the file to ensure it is indeed ASCII printable, this greatly reduces the number of false positives without checking the entire file byte by byte. With the advent of XML and CGI scripts, it is not uncommon to see HTML headers within files that are not HTML at all. Some would argue that these CGI scripts and other binary files are valuable evidence, thus the traditional method of extraction based on strictly header/footer data is available via the configuration file of Foremost.

This method of error detection is somewhat slower than just looking at the header/footer pair. However, much time is saved by not having to sift through files which do not appear to be HTML, thus increasing the productivity of the examiner. Through experimentation it was found that often small portions of CGI scripts are extracted that only contain the "<html>" and "</html>" tags embedded within the binary values. The utility of such files is minimal and thus this algorithm attempts to rectify this problem.

12. CPP (C/C++ Source Code)

Source code detection could be a useful weapon in the prosecution of hackers because Foremost could potentially recover some source code that a hacker compiled on a "victim's machine". The detection of C source code is an intriguing task as no well defined header or footer exists for these types of ASCII text files. Thus a system of markers and keyword searches is the best method for building a system which can intelligently extract these files. The fundamental marker that the CPP extraction algorithm uses is the "#include" statement which must be in source code if it wishes to use any libraries whatsoever. However this isn't fool proof; as a C file may contain only function definitions and be included or linked with another file that contains the #include statement. In addition many local exploits are short and usually only consist of a single

source file. This is a limitation that is accepted as this extraction method can be termed as a "best effort" method.

Once the first marker is found then the file is scanned to until a non ASCII printable character is reached. With this new buffer of information a series of keywords is then searched for to give added confidence that the data is in fact source code. Other keywords include "int ", "char ", and "#define ", these strings help build a "score" for the data and if the file meets the minimum score threshold then it is extracted and deemed source code. This method works reasonably well but a more sophisticated system must be implemented to "catch all" of these types of files.

B. SEARCH ALGORITHMS

1. Boyer Moore Description

The Boyer-Moore searching algorithm, described in R. S. Boyer and J. S. Moore's 1977 paper "*A Fast String Searching Algorithm"* [Ref. 22] is among the best ways known for finding a substring in a search space. Using their method it is possible to search a data space for a known pattern without having to examine all the characters in the search space. This is why it was chosen as the fundamental searching algorithm employed by Foremost. Boyer-Moore search algorithms are based on two search heuristics.

The first of these rules tell us how to search for substrings without repeats in a data space. Keep a pointer into the data space at the current search location; initialize this pointer to the start of the space plus n - 1 characters where n is the number of characters in the target string. Compare the character in the data space pointed to by this pointer with the characters in the target string. If this character does not occur in the target string, advance the pointer by n places. If the character does occur in the target string, advance the pointer by $n - p$ places where p is the position that the character in question first occurs in the target string. This process repeats until either a match is found or we have shifted past the end of the search space.

The second search heuristic applies to searching for targets with repeating patterns. Using only the rules set forth in the first heuristic will work for targets with

repeating patterns, but the search will not be as efficient as possible. By examining partial matches and repeats in the target string, though, it is possible to make more drastic pointer jumps and arrive at the match more rapidly. This type of jump is based on a table which is computed before the search begins.

Figures 9 & 10 show the improvements Boyer-Moore makes when compared with brute force search methods. Notice that Boyer-Moore completes the search in less than half the comparisons of the conventional methods.

```
For any commands
|                  compare (a to F)
and
 |                 compare (a to o)

          and
           |       compare (a to m)
           and
            |||    compare (a to a), (n to n) and (d to d)
            and
                   ---------------------------------------
                   Total of 17 comparisons.
```

Figure 9. Brute Force Search (From Ref. [23])

```
For any commands
  |                compare (d to r)
and
    |              compare (d to n)
  and
     |             compare (d to y)
   and
        |          compare (d to o)
     and
          |        compare (d to a)
        and
          |||      compare (d to d), (n to n) and (a to a)
          and
                   ---------------------------------------
                   Total of 8 comparisons.
```

Figure 10. Boyer Moore Search (From Ref. [23])

2. Algorithm Analysis

An analysis of Boyer-Moore shows that vast improvements can be achieved versus the brute force O(n^2) method. M is equal to the size of the search space and n is equal to the size of the string. The preprocessing phase has O(m+σ) time and space complexity, the searching phase has O(mn) time complexity, 3*n text character comparisons in the worst case when searching for a non periodic pattern, and O(n / m) best case performance[Ref. 22]. This added performance is the reason this algorithm is the most popular for performing text searches in many editors, but it also suits the disc carving purpose because it can be adapted to perform hexadecimal searches as well.

C. INDIRECT BLOCKS

1. UNIX File System Overview

As with other operating systems, files are not necessarily written to disk contiguously by UNIX file-systems. A file may be stored in several different blocks, seemingly randomly chosen; however, the blocks do generally adhere to a semi-contiguous structure. UNIX creates a data structure called an inode to maintain all relevant information about a file, including which disc blocks the file has been stored on. Each inode is stored sequentially in an array, so the inode itself does not affect its corresponding file size. The file system is retrieved during the boot process. The boot process contains a hard coded inode number, which represents a file location containing a boot block in memory and inode list [Ref. 24].

UNIX deals with fragmentation by redirecting its inodes. It creates "indirect blocks" for those inodes pointing to large files, where the file is stored in non-contiguous blocks on a disk. Those indirect blocks contain the addresses of the blocks containing the file, and the inode in turn contains the address of that indirect block.

2. Indirect Block Detection

Indirect block detection is an invaluable tool in successful extraction of files from a UNIX/LINUX file system. Indirect blocks are used when a file consists of more than

twelve blocks and the file system needs to store additional information so that it can keep track of all the blocks allocated to the file. The ability to detect indirect blocks, use the information stored in those blocks greatly increases the detection and extraction capabilities in UNIX file systems. Figure 11 depicts a screenshot from the debugfs program which shows the blocks that are allocated to a Power Point file. Notice that the file is larger than 12 blocks, thus it requires the usage of an indirect block (IND) located at offset 8525813. In this case, as is often the case, IND is contiguous with the rest of the blocks; however for extraction purposes it must be detected and removed.

```

Figure 11. Debugfs Screenshot

Using the UNIX program dd, we can view the structure of the indirect block. Figure 12 shows the actual indirect block used in the example Power Point file. Notice that each 4 byte chunk is the location of the remaining blocks allocated to the file. The file system uses this information in order to rebuild the file before giving it to the operating system. The fact that these blocks are usually increasing and fairly close together can be exploited by a heuristic function which detects and removes indirect blocks. The algorithm works by first analyzing the structure of the indirect block to verify that it is not simply part of the file. Verification of increasing offsets followed by a variable amount of 0's occurs. Then the differences between each offset is checked to determine whether they exceed a given threshold value to add assurance that the block under study is an indirect block. If a difference exceeds one, meaning that the offsets are

not contiguous then following logic ensues in an attempt to rebuild the file before it is handed off to the extraction algorithms.

Figure 12. Indirect Block Screenshot

One of the main problems with indirect block detection is the fact that often tools like Foremost are used on fragments of a disc. These may include just unallocated space, slack space, or maybe only a portion of a valid file-system is recoverable. In any case the offsets located in the indirect block cannot be trusted as they only hold true if the entire file-system is intact. Therefore, some assumptions must be made in order to attempt the reconstruction of non-contiguous files that contain indirect blocks. The first offset listed in the indirect block is assumed to be one more than that of the indirect block itself therefore all other offsets can be used relative to that one. Essentially the heuristic uses the remaining offsets as offsets from the first block listed in the indirect block. This works reasonably well as many indirect blocks that are not contiguous usually only contain one or two blocks that are not in order. Thus as long as the first block listed is contiguous, the algorithm performs with great success.

Another problem is the fact that the block size isn't the same across various UNIX file sizes. Thus the most common block size of 4096 bytes is tried first to see if the block

meets the detection algorithm's specifications. Failing that, then other common block sizes must be tried in order to attempt to determine what the actual block size is. This may also be accomplished by having a user defined block size, if the user knows the specific file system used, such as UFS, EXT2, or EXT3.

File system vendors often trump security for speed. This is why files are often not overwritten when they are deleted but merely have their meta-data moved to unallocated space. The EXT3 file system actually does delete the inodes and indirect blocks of a file. Some may argue that this trend negates the need for indirect block detection. But the heuristic if often useful in the case where only a portion of the file-system may be recoverable, thus leaving some indirect blocks in tact.

No data carving tool has addressed the need for indirect block detection. On UNIX file-systems the advantages are huge as, files such as office documents, multimedia, archive, and even images routinely use more than 12 blocks, thus extraction algorithms will fail. As operating systems such as Linux increase in popularity the use of EXT2/EXT3 file-systems will increase so and so will the need for these types of algorithms which can interpret the data stored in indirect blocks. See the indirect block section in chapter four for examples of how indirect block detection improves successful extraction of various files.

THIS PAGE INTENTIONALLY LEFT BLANK

IV. EXPERIMENTAL RESULTS

A. OVERVIEW

The tools used in this comparison include FTK, ILOOK, the original version of Foremost, and the modifications to Foremost presented in this paper. For testing purposes the implementation of the tool described in this paper will be referred to as Foremost 1.0.

Version 1.5 of FTK, the version current at the writing of this document, supports the following file formats: BMP, GIF, JPEG, EMF, PDF, HTML, AOL, and OLE. The capabilities of this product performed very well in experimental test cases. However, FTK only allows for carving of unallocated space thus it will not be used in the test cases as it wouldn't provide a fair comparison with products that analyze an entire disc image. However, the tool seems to use an approach similar to the one described in this paper.

ILOOK supports far more file formats than FTK but with varying success. It even provides multiple versions of extraction algorithms for the same file format. This is mainly because ILOOK can incorporate new file signatures into its data carving mechanism. For example, ILOOK contains three different extraction methods for carving JPEG files. Testing these algorithms showed that they perform relatively well but they do not catch everything and they perform at varying speeds. Overall this tool performs well but it definitely emphasizes quantity of output over quality. This can potentially become burdensome for an analyst.

B. NTFS

Brian Carrier, the main Sleuthkit developer, created a 10MB test image for testing forensic tools ability to extract jpeg data. The image is an NTFS partition containing the files listed in Table 19 below. Through experimentation it was discovered that NTFS does a very good job of storing files in contiguous memory blocks. This makes the disc carving process much easier than dealing with the indirect blocks of UNIX files systems. The MD5 of the image is "9bdb9c76b80e90d155806a1fc7846db5" and it can be downloaded at http://dftt.sourceforge.net/test8/. This image was used because of its

availability and to demonstrate the utility of the JPEG algorithm described previously in addition to ZIP, GZIP, and OLE extraction capabilities.

Num	Name	MD5	Note

Table 19. Brian Carriers JPEG test image files (From Ref. [25])

After running ILOOK against the image the following files were extracted. Note that since the image is a valid NTFS partition ILOOK has the capability to mount the

image and extract files via the meta-data. Note that this is not relevant to the disc carving capability of the tool. ILOOK uses a customizable database of file signatures to "carv" data. In essence it takes the same approach as Foremost 0.69 in that only header and footer data seems to be analyzed. Although this cannot be verified without the source code it seems that ILOOK uses a file size limit of 102,400 bytes for JPEG which explains why all files greater than that threshold were truncated.

Num	Name	MD5	Size	Note

Table 20. ILOOK results from NTFS sample image

After running the traditional version of Foremost (0.69) the following files were extracted (See Table 21 below). The older version of Foremost performed reasonably well against an image consisting mostly of simple jpeg files. In addition since only one OLE document was included in the image Foremost 0.69 was able to extract the Word Document using its NEXT search capability. The NEXT search capability allows Foremost to use the header as the footer, this approach relies on the fact that OLE documents are often written in relatively close memory space. Since they are sometimes written in groups the header of the NEXT document can be used to determine the EOF of the current document. This method works pretty well for small images but severely degrades as images grow and documents become more spread out.

Table 21. Foremost (0.69) results from NTFS sample image

Results from Foremost 1.0 are provided in Table 22 below. Note the only file that could not be fully extracted is the one located in the alternate data stream as the data portion of the file is not contiguous. The fact that 7 of 11 files matched their original md5 hash shows the precision that tailored extraction heuristics offers the disc carving arena. This is an obvious improvement over the 4 files matched by Foremost 0.69 matched and the single md5 matched by ILOOK.

Table 22. Foremost (1.0) results from NTFS sample image

C. FAT32

The FAT32 image used is a custom 62MB image I created using the mkfs tool. It was created to display the inadequacies of the current data carving tools and to show how some simple methods can be used to improve upon them. This image can be downloaded from Brian Carriers forensic testing site at http://dftt.sourceforge.net/. The drive was also overwritten with zero's to ensure that no other data would be present other than the test images. The first block of the image is also destroyed so that it cannot be mounted. Listed below in Table 23 are the files contained in the image along with their associated attributes and description. These provide the data that can be used for comparison among the different programs.

Table 23. Sample FAT32 test image

The results from Foremost version (0.69) are shown below in Table 24. Notice that version 0.69 extracted 6 out of 14 valid files, but it also generated 5 corrupted files or false positives. Two jpeg images were missed because of a variable JPEG signature (EXIF) that version 0.69 doesn't support. In addition the only reason OLE documents were successfully extracted is because they can contain garbage data at the end of the document hence the large file sizes that 0.69 extracted. This is why 00000010.doc will open successfully however it is over 1000 times as large as the original file size of 11,264

(test.ppt) bytes. The same holds for the 00000002.doc file which was originally only 19,968 bytes in size, but was ballooned to 8,402,944 bytes by 0.69! This method may be satisfactory for small files but this type of extraneous extraction really slows down the program when analyzing larger images. Version 0.69 also extracted a JPEG that had been purposely corrupted to illustrate such inadequacies. Methods such as these rely on the examiner to determine what files are readable/corrupted or not. In addition Foremost 0.69 cannot make a distinction between Word Documents and other OLE files thus it names any OLE file as it were a word document.

Table 24. Foremost (0.69) results from FAT32 sample image

The results from Foremost (1.0) are included in Table 25 below. Version 1.0 successfully recovered all 14 valid files and ignores the corrupted JPEG file (haxor2.jpg). This method also reduces the amount of redundant processing that version 0.69 does and speeds up the processing exponentially. 10 out of 14 files match their original md5sum

and the rest are no more than a few sectors off from their original size. This adds weight in a forensic context as the evidence is more precise than version 0.69 which only matches 1 out of 14 md5 hashes.

Table 25. Foremost (1.0) results from FAT32 sample image

D. EXT2/EXT3

The EXT2 image studied is a 62MB image I created from a USB thumb drive. This image along with its hash is available via the internet at http://dftt.sourceforge.net/. The drive was formatted using the mkfs program so that indirect block detection could be evaluated. After the image was constructed the meta data pertaining to mounting the image was corrupted to ensure strict carving methods would be used to extract data. The default block size chosen by the mkfs program is 1024, therefore Foremost 1.0 should detect single indirect blocks and remove them. Many of the files included in the image are larger than 12,168 bytes, thus they require at least a single indirect block.

Table 26. Sample EXT2 Image

The results from Foremost version (0.69) are shown in Table 27 below. The only file that was successfully extracted by version 0.69 was smaller than 12,168 bytes and thus didn't include any indirect blocks. Only one of the file matched its original

MD5SUM hash. 4 of the 9 files extracted are at least partially viewable. Most notably 00000001.jpg and 00000000.gif still contain their indirect blocks and thus the latter halves of the images are not-viewable. Also note that only the thumbnail of sherry.jpg was extracted because version 0.69 doesn't adequately recognize an EXIF JPEG. This example demonstrates the inadequacies of Foremost (0.69) in analyzing a UNIX file-system.

Num	Name	MD5	Size	Note
1	00000000.gif	c36a312216225baff5b0 8bba5dab00e6	19687	Partially corrupted GIF (blogo.gif)

Table 27. Foremost (0.69) results from EXT2 sample image

The results from Foremost (1.0) are included below in Table 28. The only real problem version 1.0 ran into is the fact that n_lin_ss.pdf requires a double indirect block which is not supported in this version. This extension is left as future work. 5 out of 10 MD5SUMS matched and all of the files were at least partially viewable as compared to the previous version where only 4 files were even partially discernable and only 1 MD5SUM matched. Also note that over half of the files were not readable thus this causes the examiner for time to manually extract files.

Table 28. Foremost (1.0) results from EXT2 sample image

This test case shows the case where adding 50 lines of code to a program can dramatically increase the extraction functionality of a given tool. Granted that indirect block detection is not an exact science, but it does provide more useful data when extracting files from a UNIX file system. Sample source code is provided for indirect block detection in Appendix A.

V. CONCLUSION

A. SUMMARY

With some study of file format specifications and reverse engineering of propriety formats, existing disc carving tools can be vastly improved. In addition through comparison with closed source products this paper has shown that open source tools can perform just as well, if not better than commercial forensic suites. The methods outlined in this paper can provide a file system independent program that can take advantage of file system specific information such as indirect block detection but not use them as a crutch.

Experimental results provided in this paper as well as those performed on real world machines have shown the usefulness of developing more sophisticated disc carving algorithms. As file systems and file formats become more complex so must the intelligence of these algorithms in order to preserve forensic integrity and utility.

The current implementation of the algorithms described in chapter III can be viewed in the CVS repository of Foremost at http://sourceforge.net/. At the time of this paper version 1.0 is in its testing phase, once completed it will be made available at http://foremost.sourceforge.net/.

B. PROBLEMS

The code, as provided in Foremost version 0.69, is somewhat platform dependent and needs to be rewritten to encourage portability/modularity to at least other UNIX platforms if not Windows. The main reason that this code has not been incorporated into Sleuthkit is the fact that it is very Linux dependent and cannot be easily ported to Solaris or BSD. Jesse Kornblum (The original author) is rewriting the entire program for this reason. Once this is complete, the work described in this thesis will be incorporated into the new version. The inclusion of Foremost into Sleuthkit will give added weight to the forensic suite and hopefully increase its popularity within organizations that can not afford expensive Windows based products, or wish to make use of open source solutions.

One of the main problems faced in developing a tool such as Foremost is the fact that the memory of the machine used for analysis is finite. This problem manifests itself when attempting to extract files that span our "chunk" size. The default chunk size used by Foremost is 100MB, thus large files are analyzed 100MB at a time. What are the best methods to "bridge the gap" between chunks while analyzing an image? The easy answer is to just re-read from the disk every time we find a file near the edge of a chunk, however, disk reads are inefficient and should be minimized. Foremost 1.0 uses the "max file size" approach to deal with this problem. A look ahead can be performed to meet this size. A simpler approach is to use very high end machines with large amounts of memory. The problem would be reduced as the amount of available memory grows.

C. FUTURE WORK

The creation of a standard library of file specific extraction methods so all forensic tools can have access to the same robust algorithms to carve data would be a significant capability for the forensics community. This would allow tools to focus on other areas of forensic research while having a powerful set of methods to detect and extract given file formats.

In addition to file recognition, block recognition poses a more complicated problem. As a file-system becomes more fragmented this will be a technology that must be employed in an attempt to continue the usefulness of disc carving. This is especially relevant when taking RAM images into account as paging leaves files seemingly scattered across the image. If these blocks could be detected and rebuilt to be fed to an extraction algorithm that can detect valid file formats this would greatly improve live forensic capabilities.

Improvements of OLE and GZIP extraction methods require more study than is covered in the scope of this paper. The available documentation of OLE file structure is limited. Existing methods are in place via the API and programs provided by the Chicago Project. However, these methods do not provide adequate means to determine the actual file size. OLE documents are notorious for their garbage data and wasted space. There are tools available to read and write to this "garbage" area of the file. More research and

reverse engineering are needed to be able to track this space so it can be accounted for when determining file sizes. Our experimentation using the algorithm described previously shows that one can usually determine file sizes within a block of the actual file end. This is adequate if the goal is to read the document but doesn't provide accurate results in terms of forensics as the extracted data is not identical to the actual file on this disk.

GZIP file detection lacks functionality without a GZIP decompression algorithm, as described previously. Such a method incorporated in Foremost would allow for more accurate extractions as well as the inflation of archived files on the fly.

Single indirect block detection provides a simple and useful tool to aide the forensic analysis of UNIX file-systems. However, being able to provide additional logic to rebuild files based on their single as well as double and triple indirect blocks poses a more challenging problem not addressed in this paper. Such functionality would allow better analysis of file-systems which employ smaller block sizes thus requiring more indirect blocks. In addition large multimedia files and documents could be extracted more efficiently.

APPENDIX A. SOURCE CODE

This appendix includes all files which were modified in the development of Foremost 1.0. This version is current as of 3/09/05: please go to http://foremost.sourceforge.net to get the latest copy. The main intelligence of Foremost comes from the extract.c file where all the extraction functions are fully defined.

M. FOREMOST.CONF

```
#
# Foremost configuration file
#-----------------------------------------------------------------------
#
# The configuration file is used to control what types of files foremost
# searches for. A sample configuration file, foremost.conf, is included with
# this distribution. For each file type, the configuration file describes
# the file's extension, whether the header and footer are case sensitive,
# the maximum file size, and the header and footer for the file. The footer
# field is optional, but header, size, case sensitivity, and extension are
# not!
#
# Any line that begins with a '#' is considered a comment and ignored. Thus,
# to skip a file type just put a '#' at the beginning of that line
#

# Headers and footers are decoded before use. To specify a value in
# hexadecimal use \x[0-f][0-f], and for octal use \[0-3][0-7][0-7].  Spaces
# can be represented by \s. Example: "\x4F\123\I\sCCI" decodes to "OSI CCI".
#
# To match any single character (aka a wildcard) use a '?'. If you need to
# search for the '?' character, you will need to change the 'wildcard' line
# *and* every occurrence of the old wildcard character in the configuration
# file. Don't forget those hex and octal values! '?' is equal to 0x3f and
# \063.
#
# If you would like to extract files without an extension enter the value
# "NONE" in the extension column (note: you can change the value of this
# "no suffix" flag by setting the variable FOREMOST_NOEXTENSION_SUFFIX
# in foremost.h and recompiling).
#
# The REVERSE keyword after a footer instructs foremost to search backwards
# starting from [size] bytes in the extraction buffer and working towards the
# beginning. This is useful for files like PDF's that have multiple copies of
# the footer throughout the file.  When using the REVERSE keyword you will
# extract bytes from the header to the LAST occurence of your footer within the
# window determined by the [size] of your extraction.
#
# The NEXT keyword after a footer instructs foremost to search forwards for data
# that starts with the header provided and terminates or is followed by data in
# the footer -- the footer data is not included in the output.  The data in the
# footer, when used with the NEXT keyword effectively allows you to search for
```

```
# data that you know for sure should not be in the output file.  This method for
# example, lets you search for two 'starting' headers in a document that doesn't
# have a good ending footer and you can't say exactly what the footer is, but
# you know if you see another header, that should end the search and an output
# file should be written.

# To redefine the wildcard character, change the setting below and all
# occurances in the formost.conf file.
#
#wildcard  ?

#              case    size    header                footer
#extension   sensitive
#
#------------------------------------------------------------------------
# EXAMPLE WITH NO SUFFIX
#------------------------------------------------------------------------
#
# Here is an example of how to use the no extension option. Any files
# containing the string "FOREMOST" would be extracted to a file without
# an extension (eg: 00000000,00000001)
#      NONE     y      1000     FOREMOST
#
